Background: The Limberg flap reconstruction and the Karydakis flap reconstruction are the 2 most used off-midline closure techniques in pilonidal sinus surgery. The current evidence is inconclusive as to which is the optimal technique. The aim of this systematic review and meta-analysis was to compare differences in outcomes between these 2 flap-based techniques.

Methods: We identified studies by a systematic literature search of the Embase, MEDLINE (PubMed), Cochrane Library and Google Scholar databases and studies selected as per the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) checklist. Only randomized controlled trials (RCTs) that compared the Limberg flap (standard or modified) and the Karydakis flap were included in this review.

Results: Operative time was shorter by 7 minutes in the Karydakis group than in the Limberg group (mean difference 7.00 min, 95% confidence interval [CI] 0.53 to 13.48). The seroma formation rate was significantly higher in the Karydakis cohort (odds ratio [OR] 0.36, 95% CI 0.24 to 0.56); however, after excluding studies with a high risk of bias, the sensitivity analysis showed no significant differences in seroma formation rate between the 2 techniques (OR 0.76, 95% CI 0.31 to 1.85). Other outcomes of interest showed no significant differences between the Limberg and Karydakis techniques.

Conclusion: There were no significant differences between the Limberg and Karydakis techniques. Future RCTs with strict adherence to CONSORT guidelines will further elucidate the efficacy of these surgical procedures.

Contexte : Les reconstructions à l’aide de lambeaux de Limberg et de Karydakis sont 2 des techniques de fermeture décalées de la ligne médiane les plus utilisées pour la chirurgie du sinus pilonidal. Les preuves actuelles ne permettent pas de conclure à la supériorité de l’une par rapport à l’autre. Le but de la présente revue systématique/méta-analyse était de comparer les différences de résultats entre ces 2 techniques de lambeaux.

Résultats : Les interventions ont duré 7 minutes de moins dans le groupe Karydakis que dans le groupe Limberg (différence moyenne 7,00 min, intervalle de confiance [IC] de 95% 0,53 à 13,48). Le taux de formation de séromes a été significativement plus élevé dans la cohorte Karydakis (rapport ces cotes [RC] 0,36, IC de 95% 0,24 à 0,56); par contre, après avoir exclu les études comportant un important risque de biais, l’analyse de sensibilité n’a montré aucune différence significative quant au taux de formation de séromes entre les 2 techniques (RC 0,76, IC de 95% 0,31 à 1,85). Les autres paramètres d’intérêt n’ont montré aucune différence significative entre les techniques de Limberg et de Karydakis.

Conclusion : On n’a noté aucune différence significative entre les techniques de Limberg et de Karydakis. De prochains ERC strictement conformes aux lignes directrices CONSORT permettront de préciser davantage l’efficacité de ces interventions chirurgicales.
The reported incidence rate of pilonidal disease is 25 per 100,000 people. Initially, the pathogenesis was considered to be congenital. Today, however, the theory that it is acquired is more widely accepted. Work by Georgios Karydakis, who highlighted 3 main factors contributing to pilonidal disease (loose hair, an external force that facilitates insertion of hair into the skin and an underlying vulnerability of natal cleft skin), had a pivotal role in this paradigm shift. The first 2 factors are related to personal hygiene and lifestyle, and their modulation can influence the initiation, development and recurrence of pilonidal disease. Armstrong and Barcia reported that improved hygiene, an active lifestyle and hair control in the natal cleft area decreased the need for surgical procedures and resulted in faster return to work. However, the third factor can be modified only surgically. The rhomboid, well-vascularized transposition Limberg flap was first proposed by the Russian maxillofacial surgeon Alexander Limberg (1894–1974), author of the fundamental work in plastic surgery “Mathematical principles of local plastic procedures on the surface of the human body.”

Patients with chronic pilonidal sinus disease are usually candidates for flap procedures. A chronic disease can be defined as any condition with constant or recurrent symptoms observed over several months, without any indication of spontaneous healing. Flap-based Limberg and Karydakis techniques both aim to achieve off-midline closure of the surgical defect to flatten the natal cleft. In both techniques, methylene blue is injected in the pilonidal sinuses to guide the excision. The Karydakis technique consists of an asymmetric elliptical excision of the affected area (Fig. 1). The upper and lower poles of the ellipse are placed about 2 cm to the side of the midline. Subsequently, after full-thickness mobilization of the contralateral surgical margin and fixation of the base of the flap to the sacral fascia, the skin edges are sutured off the midline. In the modified Karydakis technique, fixation to the sacral fascia is not required. The Limberg technique consists of a rhomboid-shaped excision of the affected area down to the sacral fascia (Fig. 1). The cephalic and caudal apex of the rhombus are placed about 2 cm to the side of the midline. A fasciocutaneous rhomboid flap is then created and transposed so the defect can be covered without any tension. In contrast, the classic Limberg flap consists of a symmetric rhomboid excision with its apices placed on the midline. Karydakis reported a wound complication rate of 8% and a recurrence rate of 2% for 7471 procedures. The reported recurrence rate with the Limberg technique is 5%.

Fig. 1. (A) Karydakis technique. (B) Limberg technique with rhomboid transposition flap.
The existing evidence is inconclusive as to which technique is the optimal treatment for pilonidal sinus disease. To help clarify this issue, we performed a systematic review to compare the Limberg and Karydakis flap techniques through meta-analysis of randomized controlled trials (RCTs). The primary outcomes investigated were wound infection, wound dehiscence and time to return to work. Hematoma formation, length of hospital stay, recurrence and patient satisfaction rate were secondary outcomes.

**METHODS**

This systematic review and meta-analysis was carried out in accordance with the guidelines set out in the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) checklist.

**Literature search**

We performed a systematic literature search of articles published in the last 20 years using the Embase, MEDLINE (PubMed), Cochrane Library and Google Scholar databases and free text and MeSH search terms (standard or modified Limberg flap; standard or modified Karydakis flap; pilonidal sinus surgery and disease; randomized or nonrandomized controlled trial). We also performed a grey literature search on the ClinicalTrials.gov Web site. We manually checked references of the retrieved articles for further analysis. Disagreements between the authors were resolved by consensus.

**Study selection and inclusion and exclusion criteria**

Only RCTs that compared standard or modified Limberg flap and standard or modified Karydakis flap in pilonidal sinus surgery were included in the study. All nonrandomized studies, reviews and narrative articles were excluded.

**Data extraction and outcomes**

Two reviewers (P.G. and E.B.) independently extracted the following summary data for the included studies: name of authors, patient age, operative time, wound infections, wound dehiscence, hematoma, seroma, recurrences, length of hospital stay, time to return to work and patient satisfaction.

**Risk of bias assessment of included studies**

The 2 authors independently assessed the risk of selection bias, attrition bias, detection bias, performance bias and reporting bias for each included study. We categorized the risk of bias according to the Cochrane Handbook for Systematic Reviews of Interventions as high, low or unclear.

**Definitions**

We defined operative time as time from scalpel to the skin until the last skin stitch. Wound infections and seromas were reported based on clinical findings. Culture results and wound dehiscence (partial or complete) were defined by the individual study authors. We defined length of hospital stay as the number of days from the operation day until the day of discharge. Patient satisfaction was reported as described by each of the included studies’ authors.

**Statistical analysis**

We conducted statistical analysis using Review Manager 5.3 software (Cochrane Collaboration). Heterogeneity was assessed through the $I^2$ test, and cut-off values of 25%, 50% and 75% were considered low, moderate and high, respectively. For $F$ values above 25%, both fixed- and random-effects models were used and the results compared between them. In cases in which the $F$ value was 25% or less, we used fixed-effects models throughout.

We analyzed dichotomous variables based on odds ratios (ORs) with 95% confidence intervals (CIs). For the analyzed outcomes, the reference categories were selected so that OR < 1 favoured the Limberg technique. We combined continuous variable based on both the mean difference and standardized mean difference. For studies that did not report the means and variances for the 2 groups, we estimated these values from the median, range and sample size where possible, using the technique described by Hozo and colleagues. In all analyses, the significance level was set at $p < 0.05$.

**Sensitivity analysis**

We conducted analyses of primary and secondary outcomes using both random-effects and fixed-effect models in order to assess the impact of heterogeneity on the results. In addition, we performed subgroup analysis of the studies in which the modified flap technique was used. We did not estimate publication bias because fewer than 10 studies were included in the review.

**RESULTS**

**Characteristics of included studies**

The search strategy yielded 93 papers. A further 3 papers were obtained via manual reference searching, for a total of 96 studies. After removal of duplicates, 87 studies remained. Their abstracts were screened and 41 studies were removed as they did not fulfill the inclusion criteria. The full articles of the remaining 46 studies were read. Twenty-six 1-arm studies and 11 retrospective analyses were excluded, leaving 9 studies that met the criteria...
for inclusion in this systematic review and meta-analysis (Fig. 2).

A total of 1421 patients were involved in the selected studies, of whom 773 (54.4%) underwent Limberg and 648 (45.6%) underwent Karydakis flap reconstruction. Demographic characteristics were similar between the 2 groups (Table 1). All studies included patients with chronic pilonidal disease. Five studies compared the modified Limberg flap to the Karydakis flap;\textsuperscript{15,17–19,21} those results were similar to those for the total sample (Table 2). Bali and colleagues\textsuperscript{19} enrolled only patients with recurrent disease. The most commonly used excluding criteria of the RCTs were recurrent disease, American Society of Anesthesiologists physical status class 3 or greater, diabetes, drug or alcohol addiction, renal failure and immunosuppression. Patients with laterally extended sinuses unsuitable to be included in

the fusiform excision of the Karydakis procedure were transferred to the Limberg procedure.15

**Study quality**

Generally, RCT quality was poor (Table 3). There was a widespread high risk of inadequate blinding and incomplete outcome data. Allocation was adequately concealed in 516–19 of the 9 studies. Only 1 study17 adequately addressed the sequence generation and blinding of outcome assessors, and none of the studies performed an intention-to-treat analysis for the missing data.

**Outcomes of interest**

Operative time was 7 minutes shorter in the Karydakis group than in the Limberg group (mean difference 7.00 min, 95% CI 0.53 to 13.48), although heterogeneity was extremely high (F = 99%). The seroma formation rate was significantly higher in the Karydakis group than in the Limberg group (OR 0.36, 95% CI 0.24 to 0.56, F = 19%) (Fig. 3). However, subgroup analysis including only studies with a low risk of bias showed no statistically significant difference in seroma formation rate between the 2 techniques (OR 0.76, 95% CI 0.31 to 1.85, F = 25%) (Fig. 3).

For all other outcomes (wound infection/dehiscence, hematoma, recurrence, length of hospital stay and patient satisfaction), no significant differences were found between the 2 procedures (Table 2).

**Sensitivity analysis**

Subgroup analysis of the studies including the modified Limberg flap did not show any differences compared to the total sample of studies. The differences found in seroma formation rates disappeared when studies with high risk of bias were excluded (Fig. 3, Table 2). No discrepancies were found between the results produced with fixed-effects and random-effects models.

**Discussion**

This systematic review and meta-analysis showed no remarkable differences between the Limberg and Karydakis procedures in rates of wound infection/dehiscence, hematoma, recurrence and patient satisfaction, or length of hospital stay. There were only 2 differences between the 2 techniques: operative time and seroma formation rate. In the analysis, a modest difference in operative time was

For all other outcomes (wound infection/dehiscence, hematoma, recurrence, length of hospital stay and patient satisfaction), no significant differences were found between the 2 procedures (Table 2).

*J can chir.*, Vol. 62, No. 2, avril 2019
the procedures. Arslan and colleagues reported the
not show differences in seroma formation rates between
subgroup analysis including only higher-quality studies did
in the Karydakis group. However, a
made it impossible to determine whether anesthetic type
did indeed influence operative time.

Previous authors have attributed this difference in operative
time to 2 factors: first, the classic Karydakis flap does not
require fixation at the sacral fascia, thereby reducing the
amount of operative time required. One potential con-

Seroma formation rates were slightly lower in the
Limberg group than in the Karydakis group. However, a
subgroup analysis including only higher-quality studies did
not show differences in seroma formation rates between
the 2 procedures. Arslan and colleagues reported the
highest difference in seroma formation rate between the
Limberg and Karydakis procedures (5% and 20%, respec-
tively). However, their study contained incomplete data
regarding dislodgement of drains, which made it difficult
to control for confounders. In the same study, there is con-
tradictory information regarding the length of hospital stay
and the duration of drainage and follow-up. Overall, the
patients had a mean length of hospital stay of 1.3 (standard
deviation 1.3) days. The authors reported that some
patients were discharged with their drain in situ. However,
this proportion of patients was not reflected in the study’s

Enriquez-Navascues and colleagues\textsuperscript{24} compared different surgical techniques for chronic pilonidal disease using traditional meta-analysis. By default, traditional meta-analyses can be used only to compare 2 treatment approaches. When 3 or more treatments are to be compared, network meta-analysis using either Bayesian or frequentist statistics must be used.\textsuperscript{25}

**Limitations**

The main limitation of this review is that, although the included studies were RCTs, most were of relatively low quality and had an unclear or high risk of bias: of the 9 studies, only 1 was graded as having a low risk of bias.\textsuperscript{17} Also, the studies’ populations were likely heterogeneous, as shown by the high $I^2$ value in the analysis of outcome of interests. The protocols, inclusion criteria, surgical technique and follow-up periods also differed, which make the findings not only statistically but also clinically heterogeneous. In this context, the results of this meta-analysis must be interpreted with caution.

**CONCLUSION**

Even taking the study limitations into account, the Limberg and Karydakis flap operations in adequately selected patients with pilonidal disease do not show any significant differences between them. Future RCTs should have strict selection criteria, predefined surgical outcome measures, blind outcome assessors, common methods of outcome assessment and follow-up periods of 2–3 years, and must show strict adherence to standards recommended in the CONSORT guidelines.\textsuperscript{26} These features will help further elucidate the efficacy of these 2 surgical procedures.
