Background: Peritoneal recurrences after cytoreductive surgery (CRS) and heated intraperitoneal chemotherapy (HIPEC) for appendiceal and colorectal cancers are frequent. This study aimed to evaluate the safety, technical feasibility and perioperative and long-term outcomes of repeat CRS/HIPEC in patients with recurrent peritoneal carcinomatosis of colorectal and appendiceal origin.

Methods: Data were collected from patients treated from 2000 to 2016 for recurrent peritoneal carcinomatosis from appendiceal or colorectal cancer with CRS/HIPEC at 2 specialist centres. Data on demographics, procedure details, morbidity and survival were recorded. Analyses compared the iterations of CRS/HIPEC to assess the safety and effectiveness of repeat surgery.

Results: Of all patients who underwent CRS/HIPEC in the 2 centres, 37 patients underwent a repeat procedure. Operative time was similar for the first and second surgeries (412.1 v. 412.5 min, \( p = 0.74 \)) but patients had a significantly lower peritoneal carcinoma index score with the second surgery (21.8 in the first iteration v. 9.53 in the second iteration, \( p < 0.001 \)) and significantly less blood loss (1762 mL in the first iteration v. 790 mL in the second iteration, \( p = 0.001 \)). There was a nonsignificant decrease in grade III–IV complications and there was no 30-day mortality associated with repeat procedures. For patients with colorectal cancer, median disease-free survival was 9.6 months and median overall survival was 40 months. For patients with appendiceal cancer, median disease-free survival was 15 months and overall survival was 64.4 months.

Conclusion: Repeat CRS/HIPEC procedures for recurrent appendiceal and colorectal peritoneal carcinomatosis are safe in well-selected patients, without increased morbidity or mortality, and they are associated with significant long-term survival, particularly for patients with appendiceal cancers. These results support the use of repeat CRS/HIPEC in these patients.

Contexte : Les récurrences péritonéales après une chirurgie cytoréductrice (CCR) et une chimiothérapie hyperthermique intrapéritonéale (CHIP) pour les cancers de l’appendice et colorectaux sont fréquentes. Cette étude visait à évaluer l’innocuité, la faisabilité technique et les résultats périopératoires et à long terme d’une reprise de CCR/CHIP chez les patients qui présentent une récurrence de carcinomatose péritonéale ayant son origine au niveau colorectal ou de l’appendice.

Résultats : De tous les patients soumis à des CCR/CHIP dans les 2 centres, 37 ont subi l’intervention de nouveau. Le temps opératoire a été similaire pour les premières et les deuxièmes chirurgies (412,1 c. 412,5 min, \( p = 0.74 \)), mais les patients présentaient un score de carcinomatose péritonéale beaucoup plus bas lors de la deuxième chirurgie (21,8 pour la première intervention c. 9,53 pour la seconde, \( p < 0.001 \)) et des pertes sanguines significativement moindres (1762 mL pour la première intervention c. 790 mL)}
Peritoneal carcinomatosis (PC) is defined by the presence of metastatic malignant deposits on the peritoneal surface that arise from a tumour exposed to the peritoneal cavity. It also includes tumours that arise and spread from the peritoneum itself.\(^1\)

The incidence of PC varies with tumour type. For colorectal cancers, 5%–7% of patients are diagnosed with synchronous peritoneal metastases at the time of their initial cancer diagnosis.\(^2\) For appendiceal malignancies, the incidence is reported to be 1–3 cases per million per year.\(^3\)

The prognosis for patients with these tumours has traditionally been poor.\(^4\) However, treatment via cytoreductive surgery (CRS) and heated intraperitoneal chemotherapy (HIPEC) can result in 5-year survival rates of 40% and 90% in patients with colorectal and appendiceal primary tumours, respectively.\(^5,6\)

Unfortunately, recurrence after CRS/HIPEC is very common. Recurrence after CRS/HIPEC has been reported in as many as 82% of patients with colorectal cancer after complete cytoreduction.\(^7\) For appendiceal cancers, this figure can approach 32%.\(^8\) The most common site of recurrence following CRS/HIPEC in both colorectal and appendiceal cancers is the peritoneum.\(^9\)

In our centres, patients are selected for repeat surgery on the basis of Eastern Cooperative Oncology Group (ECOG) status, absence of visceral or extra-abdominal metastases and disease extent.

Despite this high rate of recurrence, little is known about the perioperative outcomes and long-term survival benefits of repeat surgical treatment for isolated peritoneal recurrences following CRS/HIPEC. A systematic review on colorectal PC included studies reporting 3-year overall survival between 0% and 66%, with reports of 3-year disease-free survival of 14%–41.5%.\(^7\) A more recent systematic review of 91 patients reported a median survival of 20 months from the time of second CRS, with 2-year survival rates of up to 50%.\(^10\) A study of an 18-year experience with 3 or more iterations of CRS/HIPEC in patients with appendiceal malignancy reported a 3-year overall survival rate of 70%.\(^11\) This group also showed that survival was significantly affected by the completeness of cytoreduction, emphasizing the importance of patient selection. Another group reporting on 26 patients who underwent repeat CRS/HIPEC for recurrent PC of appendiceal origin reported 5-year survival rate of 35%, with morbidity and mortality rates similar to those seen with the first iteration of CRS/HIPEC.\(^3\)

There is wide variance in survival benefits and perioperative outcomes reported in the literature, as well as significant heterogeneity in the tumour types included in studies on repeat CRS/HIPEC. Further data are necessary to clarify these findings. Many of the studies on this topic present encouraging oncologic and safety results. We expect that adding another large, combined series of patients will add to the consensus regarding the feasibility and utility of repeating HIPEC/CRS after peritoneal recurrence.

The primary objective of our retrospective study was to evaluate the safety and technical feasibility of repeat CRS/HIPEC in patients with isolated peritoneal recurrence. Our secondary objective was to evaluate the effectiveness of this treatment modality with respect to survival and ultimate recurrence rate.

**METHODS**

**Study design**

We conducted a multicentre, retrospective, cross-sectional study. We included consecutive patients with appendiceal or colorectal cancer presenting with recurrent PC treated with repeat CRS/HIPEC from February 2000 to March 2016 at the Foothills Medical Centre (Calgary, Alta.) and at the Maisonneuve-Rosemont Hospital (Montréal, Que.). Both centres are university-affiliated provincial tertiary care referral centres for the treatment of PC with CRS/HIPEC, each performing more than 60 procedures per year. All patients underwent repeat CRS/HIPEC at least twice during the study period. All patients had complete cytoreductions (completeness of cytoreduction [CCR] score 0 or 1). Patients were also included regardless of their peritoneal carcinomatosis index (PCI)\(^12\) score at reoperation.

Patients were excluded if they did not undergo treatment with intraperitoneal chemotherapy. They were also excluded if they did not undergo cytoreductive surgery because their disease was deemed unresectable at the time of reoperation or if they underwent CRS but not HIPEC.
(e.g., patients who had CCR scores of 2 or more after an attempted CRS). Those who underwent CRS and HIPEC for malignancies other than appendiceal or colorectal cancer were also excluded. We did not require preoperative biopsy confirmation of recurrence, although many of the patients did have this at the time of surgery. The study was approved by the Conjoint Health Research Ethics Board at the University of Calgary and the Health Research Ethics Board at the University of Montreal.

Data sources

We queried the Synoptec/WebSMR data set in Calgary and the Montreal CRS/HIPEC database to identify an appropriate cohort of patients for this study. These data sets are prospectively maintained and capture 100% of CRS/HIPEC cases being done at these centres. Both incorporate extensive clinical data from all patients undergoing CRS/HIPEC operations. These databases were interrogated for patients who underwent repeat CRS/HIPEC surgeries within the study period. Data parameters collected included demographic parameters such as age and sex as well as tumour type and grade. We collected oncologic data such as neoadjuvant or adjuvant chemotherapy, as well as operative data such as type of intraperitoneal chemotherapy used, blood loss, transfusion requirements, operative time, PCI score preoperatively and CCR score. Finally, we collected outcome parameters such as grade III–IV complications as defined by the Clavien–Dindo classification, length of hospital stay, length of time to recurrence or death, and American Society of Anesthesiologists (ASA) score before repeat CRS/HIPEC.13,14 Data that were not available from the registries were collected by direct chart review.

Operative details

Patients in our centres who have recurrent PC must meet several criteria before being considered for repeat CRS and HIPEC. These criteria were previously published as guidelines from a pan-Canadian CRS/HIPEC working group. They include a good functional status (ECOG 0), age less than 65 years (but note that carefully selected older patients may be included), low-grade tumours, lack of evidence of extraperitoneal metastasis, and preoperative imaging suggesting that there is a possibility of achieving complete resection of gross tumour from the abdomen.15,16 For patients with colorectal cancer, we typically consider that a PCI score over 20 is a relative contraindication to CRS/HIPEC. We also consider bowel obstruction or unresectable pelvic recurrences as contraindications to CRS/HIPEC.16 Patients with colorectal PC are, in general, treated with preoperative chemotherapy (typically FOLFOX or FOLFIRI regimens) to select those most likely to benefit from CRS/HIPEC.

Patients underwent CRS as initially described by Sugarbaker and colleagues.17 A laparotomy incision was created, followed by complete lysis of adhesions, and the PCI score was calculated preoperatively to assess the extent and size of tumour implants. One or more peritoneectomy procedures were then undertaken to remove all visible disease, as well as electrofulguration of tumour nodules on the small bowel and visceral resections where necessary to remove primary tumours or sites of metastases.

Subsequently, a treatment of HIPEC was undertaken. For patients with all types of primary tumours, the most common chemotherapeutic agent used in Montreal was mitomycin C at 10–12 mg/m² in 2 L/m² of 0.9% NaCl. In Calgary, mitomycin C was given as 15 mg diluted in 3 L of 5% dextrose in water (D5W) or Dianeal solution. Alternative agents were a combination of oxaliplatin 400 mg given intraperitoneally in 2 L/m² of 0.9% NaCl in Montreal or in 3 L of D5W or Dianeal solution in Calgary, and 5-fluorouracil 800 mg given intravenously at both centres. In Montreal, the circulating time was 90 minutes for mitomycin C given intraperitoneally and 30 minutes for oxaliplatin given intraperitoneally, while in Calgary it was 60 minutes for both agents. In the second iteration of CRS/HIPEC, a different chemotherapeutic agent was used for the HIPEC than in the first iteration. These regimens varied between patients. The doses of chemotherapeutic agents used in the second iteration of surgery were not adjusted from those used for primary HIPEC procedures at each centre.

Any visceral anastomoses were then undertaken, and PCI and CCR scores were calculated at the conclusion of the procedure. CCR-0 was defined as no visible residual tumour, and CCR-1 was defined as tumour nodules no greater than 2.5 mm in size remaining. CCR-2 was defined as tumour nodules between 2.5 mm and 2.5 cm in size remaining, and CCR-3 was defined as tumour nodules greater than 2.5 cm remaining or the presence of confluent unresectable nodules.12 No HIPEC was undertaken when the CCR score was 2 or more, and these patients were not included in the final analysis.

Statistical analysis

We used descriptive statistics to evaluate patient and tumour characteristics. Means were compared using paired-sample Student t tests, and categorical variables were compared using the related-sample McNemar test. We compared all operative and outcome measures between the first and subsequent iterations of CRS/HIPEC to determine if the repeat operations were associated with significantly worse outcomes. For these calculations, the first HIPEC/CRS was considered the index case and the operative parameters were compared between it and the second CRS/HIPEC. The operative parameters and outcome measures for each patient were compared with that patient’s own variables from their initial surgery. Only
2 patients underwent more than 2 CRS/HIPEC surgeries, and therefore these data were not included in the analysis. Primary outcome measures were time to recurrence or death, operative time, length of stay and complications. Secondary measures were blood loss, CCR score, preoperative ASA score and preoperative PCI score for initial and repeat CRS/HIPEC. A p value < 0.05 was defined as statistically significant. All data were analyzed using SPSS statistical software version 24.0.

**RESULTS**

Forty-seven patients who were selected for more than 1 CRS/HIPEC during the study period. For 10 (21%) of these patients a second CRS/HIPEC was attempted but their disease was found to be unresectable at the time of laparotomy; 37 patients had successful CRS/HIPEC. These 37 patients formed the study population. All of the patients who did not have a successful second CRS/HIPEC had appendiceal PC. For these patients, median overall survival was 42.1 months from the time of PC diagnosis. There was 1 postoperative complication among these patients following the patient’s aborted second surgery, which was a pulmonary embolism. No patient died in the 30-day period following their second operation. Overall, 6 of 10 patients had died of their disease at the time of last follow-up.

Overall, approximately 1000 patients underwent primary CRS/HIPEC at the study institutions during the study period. The patients included in the study were predominantly female (65%) with a mean age of 49 years at the first CRS/HIPEC. There was 1 postoperative complication among these patients following the patient’s aborted second surgery, which was a pulmonary embolism. No patient died in the 30-day period following their second operation. Overall, 6 of 10 patients had died of their disease at the time of last follow-up.

Data on immediate surgical outcomes are summarized in Table 4. There were no differences in complication rates between iterations of CRS/HIPEC. Following their first CRS/HIPEC, 46% of patients had a Clavien–Dindo class III or IV complication, and 43% had a complication following CRS/HIPEC 2 (p = 1.00) (Table 4). These

| 3                               | 7 (25)          | 1 (11)      |          |

ASA = American Society of Anesthesiologists; CRS = cytoreductive surgery; HIPEC = heated intraperitoneal chemotherapy; PCI = peritoneal carcinomatosis index.
complications were most commonly intraabdominal abscesses requiring drainage or reoperation, but they also included thromboembolic disease, respiratory complications and ileus. Mean length of stay was shorter for CRS/HIPEC 2, (19.8 v. 28.4 d, $p = 0.06$), although this result did not reach statistical significance (Table 4). There were no instances of 30-day mortality in either iteration of surgery.

Long-term survival and recurrence data are summarized in Table 5. Mean follow-up time was 63.5 months. For patients with appendiceal primary tumours, median disease-free survival was nonsignificantly shorter following the second CRS/HIPEC (15.0 v. 17.7 mo, $p = 0.75$). For patients with colorectal primary tumours, there was also a nonsignificant trend to shorter disease-free survival after the second iteration of surgery (9.6 v. 21.6 mo, $p = 0.11$). Peritoneal or
distant disease was either persistent or recurrent in 46% of cases following the second CRS/HIPEC. Six patients (16%) died during follow-up, of whom 3 had appendiceal primary tumours and 3 had colorectal primary tumours. Median overall survival for patients with appendiceal primary tumours and colorectal primary tumours was 64.4 months (standard deviation [SD] 38.7) and 40 months (SD 12.5), respectively (Table 5). Five-year overall survival rates for appendiceal cancers and colorectal cancers were 89% and 67%, respectively (Fig. 1). At the time of last follow-up, 71% of patients with appendiceal cancer remained disease free and 100% of patients with colorectal cancer had had a recurrence (Fig. 2).

**Discussion**

Peritoneal carcinomatosis associated with colorectal or appendiceal malignancies is a relatively rare but potentially devastating pattern of metastasis. As survival from these tumours improves, the question of how best to treat recurrences of carcinomatosis without visceral metastases has arisen. One strategy that has been used is repeated CRS/HIPEC. The use of this technique is not widespread, and little is known about the perioperative and longer-term outcomes resulting from repeat CRS/HIPEC. The results of our study show that compared with the initial CRS/HIPEC surgery, repeat CRS/HIPEC surgery is associated with similar operative time, decreased blood loss, decreased transfusion requirements and similar complication rates. With a mean follow-up of 63.5 months, tumour-related mortality was low, at 16%.

A total of 54% of patients remained disease free at 5 years, of whom 71% had appendiceal primary tumours. This proportion of patients with an appendiceal primary tumour is in line with both our own institutional series and the reported literature. The proportion of patients who underwent repeat CRS/HIPEC in our series was approximately 4%. This is slightly lower than the value of 8% recently reported from another specialist centre. The difference may be a result of more conservative selection in our cases. A recently published series from our centre reported that the proportion of patients who underwent primary CRS/HIPEC with appendiceal tumours was 65.2%, and a large 2019 series reported that the proportion of patients undergoing primary CRS/HIPEC with appendiceal tumours was 73%. This is probably an effect of selection, as appendiceal PC tends to be more amenable to CRS/HIPEC as it typically has a more indolent course and is less invasive or infiltrative. This may also reflect the fact that the use of colorectal PC as an indication for CRS/HIPEC has been evolving over time, and CRS/HIPEC may not have been as frequently pursued for this indication at the earlier time points of our study. The baseline characteristics of the patients in each group differed, which points to the value of selection in these populations and the different biological behaviour of these tumours. The patients with appendiceal primary tumours had significantly higher PCI scores at their second HIPEC as well as a significantly higher proportion of low-grade tumours than the patients with colorectal primary tumours. Given that appendiceal PC is a more indolent disease, these patients may be offered repeat CRS/HIPEC even if they have more extensive disease. The higher proportion of high-grade tumours in the group with colorectal cancer may point to the fact that patients who have

CCR = completeness of cytoreduction; CRS = cytoreductive surgery; HIPEC = heated intraperitoneal chemotherapy; SD = standard deviation.
histologically aggressive tumours are more likely to have recurrences of PC.\textsuperscript{20}

An analysis of the intraoperative parameters suggests that the second CRS/HIPEC compares favourably with the first CRS/HIPEC with respect to the safety and difficulty of the operation in well-selected patients. Operative times and CCR scores were similar for the 2 iterations. It is possible that the lower burden of PC in the second iteration of surgery allowed a similarly complete cytoreduction to be performed.\textsuperscript{21} A study comparing patients with high-volume PC of appendiceal origin to those with low-volume PC reported median operating times that were 26 minutes shorter for low-volume disease (PCI score < 12).\textsuperscript{21} Intraoperative blood loss and transfusion requirements were significantly lower in the second CRS/HIPEC. Immediate postoperative outcomes were similar between the 2 iterations of surgery. Complication rates were almost identical, which would indicate that the safety of repeat CRS/HIPEC was similar to that of the initial surgery. Unfortunately, 10 (21\%) patients were found to have unresectable disease at the time of attempted repeat CRS/HIPEC. Patients who underwent unsuccessful repeat procedures certainly would have experienced increased pain and would have had to recover from surgery, which are undesirable outcomes, particularly in a palliative population. The postoperative pulmonary embolism experienced by 1 of the patients was another adverse outcome. In addition, these patients had lower median overall survival than the patients who underwent successful CRS/HIPEC. This may indicate that the surgery had a beneficial effect for the patients in whom it was successful or that the patients in whom the surgery was unsuccessful had worse tumour biology. The rate of aborted CRS may drop as the sensitivity of noninvasive imaging modalities continues to improve.

There was a trend toward decreased disease-free survival following the second CRS/HIPEC for both patients with appendiceal primary tumours and those with colorectal primary tumours: median disease-free survival was 2.7 months shorter in patients with appendiceal cancer and 12 months shorter in patients with colorectal cancer. However, neither observation was statistically significant. Other studies echo these results, with most describing shorter or similar disease-free survival following a second iteration of CRS/HIPEC.\textsuperscript{5,7,10,11} A recent systematic review of 190 patients with recurrent carcinomatosis of colorectal origin who underwent secondary CRS reported disease-free survival for the first CRS/HIPEC of up to 23 months, with the median disease-free survival for the second iteration being 13.7 months.\textsuperscript{7} Klaver and colleagues, in a study including patients with colorectal and appendiceal PC, reported a median disease-free survival of 4.5 months following repeat CRS/HIPEC (range 1–22 mo).\textsuperscript{22} In the largest study to date of repeat CRS/HIPEC for patients with appendiceal primary tumours, Yan and colleagues reported in 2007 a 5-year progression-free survival rate of 75\%,\textsuperscript{23} while Sardi and colleagues in 2013 reported a median
disease-free survival of 33.9 months in the most recently published series to report disease-free survival. Our results correspond well with those of the other groups, given that all of the patients with colorectal cancer had experienced a recurrence at 63 months, whereas only 25% of patients with appendiceal malignancies had experienced a recurrence over the same follow-up period. Interestingly, the Peritoneal Malignancy Institute in Basingstoke, United Kingdom, reported their 5-year median disease-free survival rate to be 74.9% for the primary CRS/HIPEC surgery in a series of 100 patients with appendiceal malignancies. Our results for the second iteration of CRS/HIPEC are in line with this observation, suggesting that the second iteration of CRS/HIPEC may return patients to their original prognosis.

The finding of a median overall survival of 64 months for patients with appendiceal primary tumours and 40 months for patients with colorectal primary tumours from the first CRS/HIPEC and a 5-year overall survival rate of 89% for patients with appendiceal cancers and 67% for patients with colorectal cancers compares favourably with the findings of other groups, with median overall survival being reported as between 18 and 55.7 months for patients with colon and appendiceal malignancies, respectively. A recent series from a French group reported a 5-year overall survival rate of 45.8% in patients who received an iterative curative-intent procedure after recurrence, compared with 4.7% in patients who did not. Our results provide further confirmation that intervention is likely to result in significant benefit for patients whose prognoses would otherwise be dismal. The recurrence rate of 100% for colorectal cancer and 29% for appendiceal cancer is also in accordance with the findings of other studies, with reports ranging from 22.5% to 82%, for patients with colorectal primary tumours, and from 45% to 54% for patients with appendiceal primary tumours.

These results are in the context of recently presented data from a randomized study that call into question the oncologic effectiveness of intraperitoneal chemotherapy when added to cytoreductive surgery. This study reported that there was no difference in overall survival or recurrence-free survival for patients who had HIPEC versus patients who did not, although it is notable that patients in both arms of this study underwent CRS and that the survival in both arms was exceptionally high, with median overall survival of over 41 months in both groups. This study may certainly inform future treatment of PC. However, the HIPEC regimen undertaken in this study is not the same as that used in our centre, and it is unclear whether a different intraperitoneal agent may yield better results. Furthermore, this study reports significantly better overall survival and recurrence-free survival for patients with intermediate PCI scores, suggesting that selected patients may benefit from HIPEC in addition to CRS. There were few additional complications reported with the addition of HIPEC, a finding that we have also observed in our own centres. Taken together, we feel that these findings by themselves do not justify the omission of HIPEC from our protocol, and we do believe that patients may derive benefit from intraperitoneal chemotherapy in addition to cytoreductive surgery.

It is also possible that the encouraging median overall survival in our study and other series is related to the increasing efficacy of systemic chemotherapy. Advances in systemic therapies for cancers of colorectal and other origins are progressing at an impressive rate. However, a recent meta-analysis performed on 10,553 patients with colorectal PC from 14 randomized trials described a median overall survival of 17.1 months in patients given combination chemotherapy and targeted therapy. The median overall survival for patients who received chemotherapy alone was 16.3 months. None of the patients in this study received CRS or HIPEC for their disease. These survival times are dramatically shorter than those seen for CRS/HIPEC in our study. This result from a very large patient sample suggests that patients may derive some benefit from CRS/HIPEC.

Our findings indicate that repeat CRS/HIPEC is technically feasible and appropriate in well-selected patients. Our study is from 2 institutions that perform a high volume of these surgeries (approximately 1000 between the 2 centres during the study period). Additional strengths of our study are that the surgeries were performed by only 5 surgeons during the study period and that the second surgery was almost always performed by the same surgeon as the first. This means that our data are very consistent in nature. Our study is also larger than many studies on this topic, given that the average number of patients in prior studies ranged from 2 to 125.

Limitations

A limitation of this study is its retrospective nature and the fact that HIPEC chemotherapy and perfusion duration were not standardized between the study sites. However, we do not believe that this had a significant impact as patients were selected for repeat procedures according to similar criteria at the 2 sites. In addition, although this is a relatively large patient series for this type of surgery, the numbers of patients are small, limiting the statistical certainty of our conclusions. These patients were highly selected, representing the healthiest patients with the best possible tumour biology. The study is also limited by the lack of a control group.

Conclusion

The results of this study show that repeat CRS/HIPEC surgery is safe, effective and technically feasible in well-selected patients. Compared with the initial CRS/HIPEC, we achieved similar complication rates, as well as lower
operative times and intraoperative blood loss in the second iteration of surgery. We also achieved long-term disease-free and overall survival for patients with a second recurrence of PC, particularly in the population with appendiceal cancer. We feel that this indicates that patients who have evidence of isolated peritoneal recurrence after CRS/HIPEC surgery should be considered for possible repeat surgery in a tertiary centre.
